1. Abstract

39

1: Wildlife monitoring technology has advanced rapidly and the use of remote sensors such as camera traps, and acoustic detectors is becoming common in both the terrestrial and marine environments. Current capture-recapture or distance methods to estimate abundance or density require individual recognition of animals or knowing the distance of the animal from the sensor, which is often difficult. A method without these requirements, the random encounter model (REM), has been successfully applied to estimate animal densities from count data generated from camera traps. However, count data from acoustic detectors do not fit the assumptions of the REM due to the directionality of animal signals.

2: We developed a generalised REM (gREM), to estimate absolute animal density
from count data from both camera traps and acoustic detectors. We derived the
gREM for different combinations of sensor detection widths and animal signal
widths (a measure of directionality). We tested the accuracy and precision of this
model using simulations of different combinations of sensor detection widths and
animal signal widths, number of captures, and models of animal movement.

3: We find that the gREM produces accurate estimates of absolute animal density
for all combinations of sensor detection widths and animal signal widths. However, larger sensor detection and animal signal widths were found to be more precise. While the model is accurate for all capture efforts tested, the precision of the
estimate increases with the number of captures. We found no effect of different
animal movement models tested on the accuracy and precision of the gREM.

4: We conclude that the gREM provides an effective method to estimate absolute animal densities from remote sensor count data over a range of sensor and animal signal widths. The gREM is applicable for use for count data obtained in both marine and terrestrial environments, visually or acoustically (e.g., big cats, sharks, birds, bats and cetaceans). As sensors such as camera traps and acoustic detectors become more ubiquitous, the gREM will be increasingly useful for monitoring animal populations across broad spatial, temporal and taxonomic scales.

2. Introduction

70

96

Animal population density is one of the fundamental measures needed in ecol-71 ogy and conservation. The density of a population has important implications 72 for a range of issues such as sensitivity to stochastic fluctuations (??) and risk 73 of extinction (?). Monitoring animal population changes in response to anthropogenic pressure is becoming increasingly important as humans modify habi-75 tats and change climates as never before (?). Sensor technology, such as camera 76 traps (??) and acoustic detectors (???) are becoming increasingly used to monitor 77 changes in animal populations (??), as they are efficient, relativity cheap and non-78 invasive (?), allowing for surveys over large areas and long periods. However, the problem of converting sampled count data to estimates of density remains as efforts must be made to account for detectability of the animals (?).

Methods do already exist for estimating animal density if the distance between 82 the animal and the sensor can be estimated (e.g., capture-mark recapture methods 83 (?) and distance sampling (?)). However, these methods often require additional 84 information that may not be available. For example, capture-mark-recapture meth-85 ods (????) require recognition of individuals; distance methods require a distance 86 estimation of how far away individuals are from the sensor barlow2005estimates, 87 marques2011estimating. The development of the random encounter model (REM) (a modification of a gas model) enabled animal densities to be estimated from unmarked individuals of a known speed, and sensor detection parameters (?). The REM method has been successfully applied to estimate animal densities from camera trap surveys (??). However, extending the REM method to other types of 92 sensors (for example acoustic detectors) is more problematic, because the origi-93 nal derivation assumes a relatively narrow sensor width (up to $\pi/2$ radians) and that the animal is equally detectable irrespective of its heading (?). 95

Whilst these restrictions are not problematic for most camera trap makes (e.g. Reconyx, Cuddeback), the REM could not be used to estimate densities from camera traps with a wider sensor width (e.g. canopy monitoring with fish eye lens

99 (?)). Additionally, the REM method would not be useful in estimating densities 100 from acoustic survey data as the acoustic detector angles are often wider than $\pi/2$ 101 radians. Acoustic detectors are designed for a range of diverse tasks and environ-102 ments (?), which will naturally lead to a wide range of sensor detection widths 103 and detection distances. In addition to this, calls emitted by many animals are 104 directional (breaking the assumption of the REM method).

127

128

129

There has been a sharp rise in interest around passive acoustic detectors in recent years, with a 10 fold increase in publications in the decade between 2000 and 2010 (?). Acoustic monitoring is being developed to study many aspects of ecology, including the interactions of animals and their environments (??), the presence and relative abundances of species (?), and biodiversity of an area (?).

Acoustic data suffers from many of the problems associated with data from camera trap surveys in that individuals are often unmarked so capture-make-111 recapture methods cannot be used to estimate densities. In some cases the dis-112 tance between the animal and the sensor is known, for example when an array of 113 sensors and the position of the animal is estimated by triangulation (?). In these 114 situations distance-sampling methods can be applied, a method typically used for 115 marine mammals (?). However, in many cases distance estimation is not possible, 116 for example when single sensors are deployed, a situation typical in the majority 117 of terrestrial acoustic surveys (??). In these cases, only relative measures of local 118 abundance can be calculated, and not absolute densities. This means that comparison of populations between species and sites is problematic without assuming 120 equal detectability (?). Equality detectability is unlikely because of differences in 121 environmental conditions, sensor type, habitats, species biology. 122

In this study we create a generalised REM (gREM), as an extension to the camera trap model of (?), to estimate absolute density from count data from acoustic detectors, or camera traps, where the sensor width can vary from 0 to 2π radians, and the signal given off from the animal can be directional. We assessed the accuracy and precision of the gREM within a simulated environment, by varying the sensor detection widths, animal signal widths, number of captures and models of animal movement. We use the simulation results to recommend best survey practice for estimating animal densities from remote sensors.

3. Methods

131

3.1. Analytical Model. The REM presented by (?) adapts the gas model to model 132 count data from camera trap surveys. The REM is derived assuming a stationary 133 sensor with a detection width less than $\pi/2$ radians. However, in order to apply 134 this approach more generally, and in particular to acoustic detectors, we need both 135 to relax the constraint on sensor detection width, and allow for animals with di-136 rectional signals. Consequently, we derive the gREM for any detection width, θ , 137 between 0 and 2π with a detection distance r giving a circular sector within which 138 animals can be captured (the detection zone)(Figure 1). Additionally, we model 139 the animal as having an associated signal width α between 0 and 2π (Figure 1, see Appendix S1 for a list of symbols). We start deriving the gREM with the simplest situation, the gas model where $\theta = 2\pi$ and $\alpha = 2\pi$. 142

3.1.1. *Gas Model*. Following ?, we derive the gas model where sensors can capture animals in any direction and animal's signal is detectable from any direction($\theta = 2\pi$ and $\alpha = 2\pi$). We assume that animals are in a homogeneous environment, and move in straight lines of random direction with velocity v. We allow that our stationary sensor can capture animals at a detection distance r and that if an animal moves within this detection zone they are captured with a probability of one, while animals outside the zone are never captured.

In order to derive animal density, we need to consider relative velocity from 150 the reference frame of the animals. Conceptually, this requires us to imagine that 151 all animals are stationary and randomly distributed in space, while the sensor 152 moves with velocity v. If we calculate the area covered by the sensor during the 153 survey period we can estimate the number of animals the sensor should capture. 154 As a circle moving across a plane, the area covered by the sensor per unit time is 155 2rv. The number of expected captures, z, for a survey period of t, with an animal 156 density of D is z = 2rvtD. To estimate the density, we rearrange to get D = z/2rvt. 157

3.1.2. gREM derivations for different detection and signal widths. Different combinations of θ and α would be expected to occur (e.g., sensors have different detection widths and animals have different signal widths). For different combinations θ and α , the area covered per unit time is no longer given by 2rv. Instead of the size

of the sensor detection zone having a diameter of 2r, the size changes with the approach angle between the sensor and the animal. For any given signal width and detector width and depending on the angle that the animal approaches the sensor, the width of the area within which an animal can be detected is called the profile, p. The size of the profile (averaged across all approach angles) is defined as the average profile \bar{p} . However, different combinations of θ and α need different equations to calculate \bar{p} .

We have identified the parameter space for the combinations of θ and α for

We have identified the parameter space for the combinations of θ and α for which the derivation of the equations are the same (defined as sub-models in the gREM) (Figure 2). For example, the gas model becomes the simplest gREM sub-model (upper right in (Figure 2) and the REM from (?) is another gREM sub-model where $\theta < \pi/2$ and $\alpha = 2\pi$. We derive one gREM sub-model SE2 as an example below (where $4\pi - 2\alpha < \theta < 2\pi$, $0 < \alpha < \pi$) (see Appendix S2 for other gREM sub-models).

3.1.3. Example derivation of SE2. In order to calculate \bar{p} , we have to integrate over

176

the focal angle, x_1 (Figure 3a). This is the angle taken from the centre line of the 177 sensor. Other focal angles are possible (x_2, x_3, x_4) and are used in other gREM 178 sub-models (see Appendix S2). As the size of the profile depends on the approach 179 angle, we present the derivation across all approach angles. When the sensor is 180 directly approaching the animal $x_1 = \pi/2$. 181 Starting from $x_1 = \pi/2$ until $\theta/2 + \pi/2 - \alpha/2$, the size of the profile is $2r \sin \alpha/2$ 182 (Figure 3b). During this first interval, the size of α limits the width of the profile. When the animal reaches $x_1 = \theta/2 + \pi/2 - \alpha/2$ (Figure 3c), the size of the profile is 184 $r\sin(\alpha/2) + r\cos(x_1 - \theta/2)$ and the size of θ / and α both limit the width of the profile 185 (Figure 3c). Finally, at $x_1 = 5\pi/2 - \theta/2 - \alpha/2$ until $x_1 = 3\pi/2$, the width of the profile 186 is again $2r \sin \alpha/2$ (Figure 3d) and the size of α again limits the width of the profile. 187 The profile width p for π radians of rotation (from directly towards the sensor 188 to directly behind the sensor) is completely characterised by the three intervals 189 (Figure 3b–3d). Average profile width \bar{p} is calculated by integrating these profiles 190 over their appropriate intervals of x_1 and dividing by π which gives

$$\bar{p} = \frac{1}{\pi} \left(\int_{\frac{\pi}{2}}^{\frac{\pi}{2} + \frac{\theta}{2} - \frac{\alpha}{2}} 2r \sin \frac{\alpha}{2} dx_1 + \int_{\frac{\pi}{2} + \frac{\theta}{2} - \frac{\alpha}{2}}^{\frac{5\pi}{2} - \frac{\theta}{2} - \frac{\alpha}{2}} r \sin \frac{\alpha}{2} + r \cos \left(x_1 - \frac{\theta}{2} \right) dx_1 + \int_{\frac{5\pi}{2} - \frac{\theta}{2} - \frac{\alpha}{2}}^{\frac{3\pi}{2}} 2r \sin \frac{\alpha}{2} dx_1 \right)$$

$$= \frac{r}{\pi} \left(\theta \sin \frac{\alpha}{2} - \cos \frac{\alpha}{2} + \cos \left(\frac{\alpha}{2} + \theta \right) \right)$$

$$= qn \ 2$$

We then, as with the gas model, use this expression to calculate density

$$D = z/vt\bar{p}.$$
 eqn 3

Rather than having one equation that describes \bar{p} globally, the gREM must be

split into submodels due to discontiunous changes in p as α and β change. These discontinuities can occur for a number of reasons such as a profile switching between being limited by α and θ , the difference between very small profiles and profiles of size zero and the fact that the width of a sector stops increasing once the central angle reaches π radians (i.e., a semi circle is just as wide as a full circle.) As a visual example, if α is small, there is an interval between Fig. 3c and 3d where the 'blind spot' would prevent animals being detected at all giving p = 0. This would require an extra integral in our equation as simply putting our small value of α into eqn 1 would not give us this integral of p = 0. gREM submodel specifications were done by hand, and the integration was done using SymPy (?) in Python (Appendix S3). The gREM submodels were checked by confirming that: 1) submodels adjacent in parameter space were equal at the boundary between them; 2) submodels that border $\alpha = 0$ had p = 0 when $\alpha = 0$; 3) average profile widths \bar{p} were between 0 and 2r and; 4) each integral, divided by the range of angles that it was integrated over, was between 0 and 2r. The scripts for these tests are included in Appendix S3 and the R (?) implementation of the gREM is given in Appendix S4.

212 3.2. **Simulation Model.** We tested the accuracy and precision of the gREM by de-213 veloping a spatially explicit simulation of the interaction of sensors and animals 214 using different combinations of sensor detection widths, animal signal widths, 215 number of captures, and models of animal movement. 100 simulations were run

where each consisted of a 7.5 km by 7.5 km square (with periodic boundaries). A stationary sensor of radius r was set up in the exact centre of each simulation, cov-217 ering 7 sensor detection widths θ between 0 and 2π (2/9 π , 4/9 π , 6/9 π , 8/9 π , 10/9 π , 218 $14/9\pi$, 2π). Each simulation was populated with a density of 70 animals km⁻², cal-219 culated from the equation in? as the expected density of mammals of weigh-220 ing 1 g. This density therefore represents the highest likely density of indivudals, 221 given that the smallest mammal is around 2 g?. A total of 3937 individuals per 222 simulation were created which were placed randomly at the start of the simula-223 tion. Individuals were assigned 11 signal detection widths α between 0 and π 224 $(1/11\pi, 2/11\pi, 3/11\pi, 4/11\pi, 5/11\pi, 6/11\pi, 7/11\pi, 8/11\pi, 9/11\pi, 10/11\pi, \pi).$ 225 Each simulation lasted for N steps (14400) of duration T (15 minutes) giving a 226 total duration of 150 days. The individuals moved within each step with a distance d, with an average speed, v. d, was sampled from a normal distribution with 228 mean distance, $\mu_d = vT$, and standard deviation $\sigma_d = vT/10$. An average speed, 229 $v = 40 \,\mathrm{km} \,\mathrm{days}^{-1}$, was chosen as this represents the largest day range of terrestrial 230 animals (?), and represents the upper limit of realistic speeds. At the end step, 231 individuals were allowed to either remain stationary for a time step (with a given 232 probability, S), change direction (with a maximum angle, A) between 0 and π . This 233 resulted in 7 different movement models where: (1) simple movement, where S 234 and A = 0; (2) stop-start movement, where (i) S = 0.25, A = 0, (ii) S = 0.5, A = 0, (iii) 235 S=0.75, A=0; (3) random walk movement, where (i) S=0, $A=\pi/3$, (ii) S=0, $A=\pi/3$ = $2\pi/3$, iii) S = 0, $A = \pi$. Individuals were counted as they moved in and out of the 237 detection zone of the sensor per simulation. 238 We calculated the estimated animal density from the gREM by summing the 239 number of captures per simulation and inputting these values into the correct 240 gREM submodel. gREM accuracy was determined by comparing the density in 241 the simulation with the estimated density. High accuracy is indicated by the mean 242 difference between the estimated and actual values not being significantly differ-243 ent from zero (Wilcoxon signed-rank test). gREM precision was determined by 244 the standard deviation of estimated densities. We used this method to compare 245 the accuracy and precision of all the gREM submodels. As these submodels are derived for different combinations of α and θ , the accuracy and precision of the submodels was used to determine the impact of different values of α and θ .

The influence of the number of captures and animal movement models on accu-249 racy and precision was investigated using 4 different gREM submodels represen-250 tative of the range α and θ values (submodels NW1, SW1, NE1, and SE3, Figure 2). 251 Using these four submodels, we calculated how long the simulation needed to 252 run to generate a range of different capture numbers (from 10 to 100 captures in 253 10 unit intervals), and estimated animal density. These estimated densities were 254 compared to the real density to assess the impact on the accuracy and precision 255 on the gREM of different simulation lengths. We also used these four submodels 256 to compare the accuracy and precision of a simple movement model, to stop-start 257 movement models and random walk movement models. The gREM assumes that individuals move continuously with straight-line movement (simple movement 259 model) and we therefore assessed the impact of breaking the gREM assumptions. 260

4. Results

4.1. **Analytical model.** The equation for \bar{p} has been newly derived for each submodel in the gREM, except for the gas model and REM which have been calculated previously. However, many models, although derived separately, have the same expression for \bar{p} . Figure 4 shows the expression for \bar{p} in each case. The general equation for density, using the correct expression for \bar{p} is then substituted into eqn 3. Although more thorough checks are performed in Appendix S3, it can be seen that all adjacent expressions in Figure 4 are equal when expressions for the boundaries between them are substituted in.

4.2. Simulation model.

247

248

261

270

4.2.1. *gREM submodels*. All gREM submodels showed a high accuracy, i.e., the mean difference between the estimated and actual values was not significantly different from zero across all models, corrected for multiple tests (all gREM sub models Wilcoxon signed-rank test, p > 0.002)(Figure 5). However, the precision of the submodels do vary, where the gas model is the most precise and the SW7 sub

model the least precise, having the smallest and the largest interquartile range, respectively (Figure 5). The standard deviation of the error between the estimated
and true densities is strongly related to both the sensor and signal widths (Figure 6), such that larger widths have lower standard deviations (greater precision).
However, even smaller sensor and signal widths have a relativity high level of
precision.

4.2.2. Number of captures. Within the four gREM submodels tested (NW1, SW1, SE3, NE1), the accuracy was not affected by the number of captures, where the mean difference between the estimated and actual values was not significantly different from zero across all capture rates, corrected for multiple tests (all gREM sub models Wilcoxon signed-rank test, p > 0.008)(Figure 7). However, the precision was dependent on the number of captures across all four of the gREM submodels, where precision increases as number of captures increases(Figure 7). For all gREM submodels, the the coefficient of variation falls to 10% at 100 captures.

4.2.3. Movement models. Within the four gREM submodels tested (NW1, SW1, SE3, NE1), neither the accuracy or precision was affected by the amount of time spent 291 stationary. The mean difference between the estimated and actual values was not 292 significantly different from zero for each category of stationary time (0, 0.25, 0.5 293 and 0.75), corrected for multiple tests (all gREM sub models Wilcoxon signed-rank 294 test, p >0.12)(Figure 8a). Altering the maximum change in direction in each step 295 (0, pi/3, 2pi/3, and pi) did not affect the accuracy or precision of the four gREM 296 submodels tested (all gREM sub models Wilcoxon signed-rank test, p >0.05)(Fig-297 ure 8b). 298

5. Discussion

299

300

301

302

303

We have developed the gREM such that it can be used to estimate density from acoustic sensors and camera traps. This has entailed a generalisation of the gas model and the REM in (?) to be applicable to any combination of sensor width and signal directionality. We have used simulations to show, as a proof of principle, that these models are accurate and precise. The precision of the gREM was

found to be dependent on the width of the sensor and the call, and the number of captures.

5.1. Analytical model. The gREM was derived for different combinations of α and θ resulting in 25 different submodels, the expression for \bar{p} are equal for many 308 of these submodels resulting in 8 different equations including the previously de-309 rived gas model and REM. These submodels were tested for consistency with adja-310 cent expressions being equal at their boundaries. These new submodels will allow 311 researchers to evaluate the absolute density of animals that have previously been 312 difficult to study with noninvasive methods such as remove sensors. The gREM 313 allows the data from acoustic detectors to be used where an animal has a direc-314 tional calls, this could be used for a range of animals including bats, songbirds, 315 Cetaceans and forest primates.

There are a number of positive extensions to the gREM which could be developed in the future. The original gas model was formulated for the case where both 318 subjects, either animal and detector, or animal and animal, are moving (?). Indeed 319 any of the models with animals that are equally detectable in all directions ($\alpha = 2\pi$) 320 can be trivially expanded for moving by substituting the sum of the average ani-321 mal velocity and the sensor velocity for v as used here. However, when the animal 322 has a directional call, the extension becomes less simple. The approach would be 323 to calculate again the mean profile width. However, for each angle of approach, 324 one would have to average the profile width for an animal facing in any direction 325 (i.e. not necessarily moving towards the sensor) weighted by the relative velocity of that direction. There are a number of situations where a moving detector and 327 animal could occur and as such may be advantage to have a method of estimating 328 densities from the data collected, e.g. an acoustic detector based off a boat when 329 studying Cetacea or sea birds (?). Another interesting, and so far unstudied prob-330 lem, is edge effects caused by trigger delays (the delay between sensing an animal 331 and attempting to record the encounter) and time expansion acoustic detectors 332 which repeatedly turn on an off during sampling. Both of these have potential 333 biases as animals can move through the detection zone without being detected.

The models herein are formulated assuming constant surveillance and so the error quickly becomes negligible. For example, if it takes longer for the recording device to be switched on than the length of some animal calls there could be a systematic underestimation of density.

5.2. Accuracy and Precision. We tested each of the gREM submodels for accuracy 339 and precision through a simulation. All the submodels produced estimated den-340 sities that were not significantly different from the true density of the simulation. 341 Therefore based on these simulations we believe that the gREM has the poten-342 tial to produce accurate estimates for many different species, using either camera 343 traps or acoustic detectors. However the precision of the gREM differed between 344 submodels. For example, when the sensor and signal width were smaller then the 345 precision of the model was reduced, so when choosing a sensor for use in a gREM 346 study the detection width should be maximised, and if the study species has a narrow signal directionality other aspects of the study protocol should be used to 348 compensate. 349

The precision of the gREM is greatly affected by the number of captures that are collected, the coefficient of variation falls dramatically between 10 and 60 captures and then after this continues to slowly reduce. At 100 captures the submodels reach 10% coefficient of variation, and therefore we believe at this point the models are precise. The length of surveys in the field will need to be adjusted so that enough data is collected to reach this level of precision, populations of fast moving animals or populations with large densities will require less survey effort than those with slow moving or low densities.

355

356

357

358

359

360

361

362

363

364

365

The gREM was both accurate and precise for all the movement models we tested against, stop-start movement and correlated random walks. However these movement models are still simple representations of true animal movement which often consist of multiple be dependent on multiple factors such as behavioural state and and existence of home ranges (?). The accuracy of the gREM may be affected by the interaction between the movement model and the size of the detection radius. In figure 8b we studied a relatively long step length compared to the size of the detection radius, and therefore the chance of catching the same animal

multiple times within a short space of time was reduced. However if the ratio of step length to detection radius was smaller then this may decrease the precision of the model, however this should not decrease its accuracy.

Although we have used simulations to validate the gREM submodels, much 369 more robust testing is needed. Although difficult, proper field test validation 370 would be required before the models could be fully trusted. The REM (?) has al-371 ready been field tested, and both? and? both found that the REM was an effective 372 manner of estimating animal densities (??). In some taxa gold standard methods 373 of estimating animal density exist, such as capture mark recapture. Where these 374 gold standard exist, and have been proved to work, a simultaneous gREM study 375 could be completed to test the accuracy under field conditions. An easier way to 376 continue to evaluate the models is to run more extensive simulations which break the assumptions of the analytical models. The main element that cannot be ana-378 lytically treated is the complex movement of real animals. Therefore testing these 379 methods against true animal traces, or more complex movement models would be 380 required. 381

Within the simulation we have assumed an equal density across the entire world,
however in a field environment the situation would be much more complex, with
additional variation coming from local changes in density between camera sites.
In the simulation we ran the speed of the animal as 40 km days⁻¹, the largest day
range of terrestrial animals (?), other speed values should not alter the accuracy
or the precision of the gREM. We also assume perfect knowledge of the average
speed of an animal and size of the detection zone, and instant triggering of the
camera. All of which may lead to possible bias or a decrease in precision.

5.3. Implications for conservation. The gREM is therefore available for the estimation of density of a number of taxa of importance to conservation, zoonotic diseases and ecosystem services. The models provided are suitable for certain groups for which there are currently no, or few, effective methods for density estimation.

Any species that would be consistently recorded at least once when within range of a detector would be a suitable subject for the gREM, such as bats (?), songbirds

(?), Cetaceans (?) or forest primates (?). Within increasing technological capabilities, this list of species is likely to increase dramatically.

Importantly the methods are noninvasive and do not require human marking or naturally identifying marks (as required for mark-recapture models). This makes them suitable for large, continuous monitoring projects with limited human resources. It also makes them suitable for species that are under pressure, species that cannot naturally be individually recognised or species that are difficult or dangerous to catch.

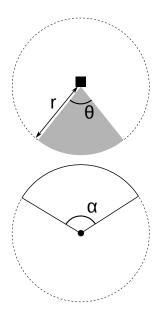

FIGURE 1. Representation of sensor detection width and animal signal width. The filled square and circle represent a sensor and an animal, respectively; θ , sensor detection width (radians); r, sensor detection distance; dark grey shaded area, sensor detection zone; α , animal signal width (radians). Dashed lines around the filled square and circle represents the maximum extent of θ and α , respectively.

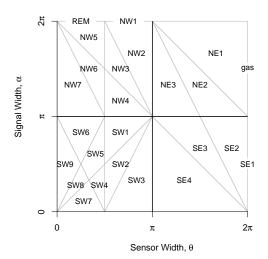

FIGURE 2. Locations where derivation of the average profile \bar{p} is the same for different combinations of sensor detection width and animal signal width. Symbols within each polygon refer to each gREM submodel named after their compass point, except for Gas and REM which highlight the position of these previously derived models within the gREM. Symbols on the edge of the plot are for submodels with $\alpha, \theta = 2\pi$

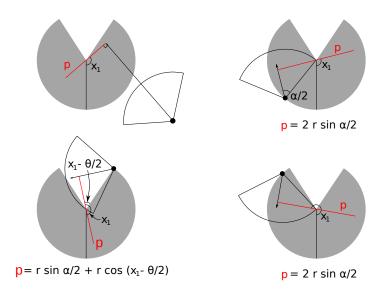

FIGURE 3. An overview of the derivation of SE2. The filled circles represent animals, with the animal signal shown as a unfilled sector and the direction of movement shown as an arrow. The detection zone of the sensors are shown as filled grey sectors with a detection distance of r. The SYMBOL shows the direction the sensor is facing; θ , sensor detection width; α , animal signal width. The profile p (the line an animal must pass through in order to be captured) is shown in red and x_1 is the focal angle, where (a) shows the location of x_1 . The derivation of p changes as the animal approaches the sensor from different directions where (b) is the derivation of p when x_1 is in the interval $\left[\frac{\pi}{2}, \frac{\pi}{2} + \frac{\theta}{2} - \frac{\alpha}{2}\right]$, (c) p when x_1 is in the interval $\left[\frac{\pi}{2}, \frac{\pi}{2} - \frac{\theta}{2} - \frac{\alpha}{2}, \frac{3\pi}{2}\right]$. The resultant equation for p is shown beneath each figure.

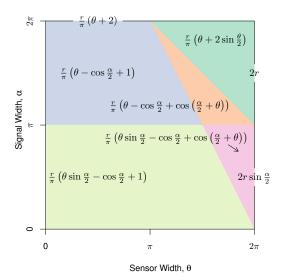

FIGURE 4. Expressions for the average profile width, \bar{p} , given sensor and signal widths. Despite independent derivation within each block, many models result in the same expression. These are collected together and presented as one block of colour. Expressions on the edge of the plot are for submodels with α , $\theta = 2\pi$.

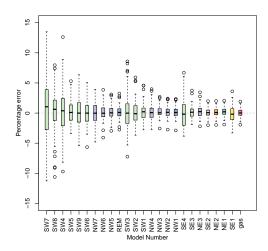

FIGURE 5. Simulation model results of the accuracy and precision for gREM submodels. The precentage error between estimated and true density for each gREM sub model is shown within each box plot, where the black line represents the median percentage error across all simulations, boxes represent the the middle 50% of the data. Box colours correspond to the expressions for average profile width \bar{p} given in Figure 4.

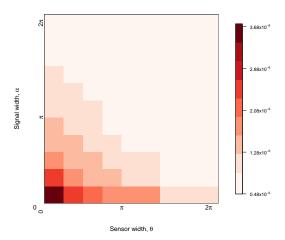

FIGURE 6. Simulation model results of the gREM precision given a range of sensor and signal widths, shown by the standard deviation of the error between the estimated and true densities. Standard deviations are shown from deep red to pink, representing high to low values between 0.483×10^{-6} to 3.74×10^{-6} .

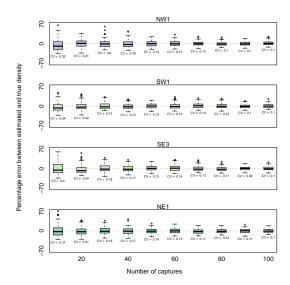

FIGURE 7. Simulation model results of the accuracy and precision of four gREM submodels (NW1, SW1, SE3 and NE1) given different numbers of captures. The percentage error between estimated and true density within each gREM sub model for capture rate is shown within each box plot. Sensor and signal widths vary between submodels. The colour of each box plot corresponds to the expressions for average profile width \bar{p} given in Figure 4.

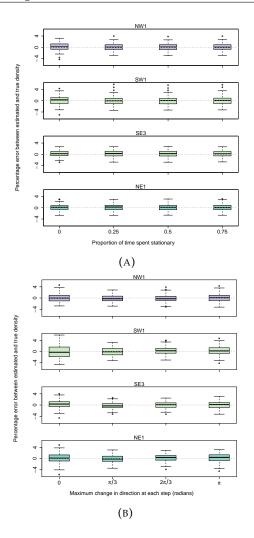

FIGURE 8. Simulation model results of the accuracy and precision of four gREM submodels (NW1, SW1, SE3 and NE1) given different movement models where (A) amount of time spent stationary (stop-start movement) and (B) maximum change in direction at each step (correlated random walk model). The percentage error between estimated and true density within each gREM sub model for the different movement models is shown within each box plot. The simple model is represented where time and maximum change in direction equals 0. The colour of each box plot corresponds to the expressions for average profile width \bar{p} given in Figure 4.
